16. Abstract

Numerous mathematical models of the interaction of radiation with vegetation canopies have been developed over the last two decades. However, data with which to exercise and validate these models have been scarce. During three days in the summer of 1980, experiments were conducted with the objective of gaining insight about the effects of solar illumination and view angles on soybean canopy reflectance. In concert with these experiments, extensive measurements of the soybean canopies were obtained.

This document is a compilation of the bidirectional reflectance factors; agronomic characteristics; canopy geometry; and leaf, stem, and pod optical properties of the soybean canopies. These data sets should be suitable for use with most vegetation canopy reflectance models.

SOYBEAN CANOPY REFLECTANCE MODELING DATA SETS

ABSTRACT

Numerous mathematical models of the interaction of radiation with vegetation canopies have been developed over the last two decades. However, data with which to exercise and validate these models have been scarce. During three days in the summer of 1980, experiments were conducted with the objective of gaining insight about the effects of solar illumination and view angles on soybean canopy reflectance. In concert with these experiments, extensive measurements of the soybean canopies were obtained.

This document is a compilation of the bidirectional reflectance factors; agronomic characteristics; canopy geometry; and leaf, stem, and pod optical properties of the soybean canopies. These data sets should be suitable for use with most vegetation canopy reflectance models.

SOYBEAN CANOPY REFLECTANCE MODELING DATA SETS

INTRODUCTION

This document is a compilation of data sets of bidirectional reflectance factors, agronomic characteristics, canopy geometry, and canopy optical parameters of soybeans acquired during the summer of 1980. The data collection techniques and preliminary results first appeared in Ranson et al. (1981) and were further developed by Ranson et al. (1985). In the meantime, portions of these data were distributed to the scientific community and numerous reviewed articles have appeared in the literature as a result (e.g., Kimes and Kirchner, 1982; Cooper et al., 1982; Goel and Strebel, 1983; Goel and Strebel, 1984; Goel and Thompson, 1984a; Goel and Thompson, 1984b; Chance and LeMaster, 1985; Strebel, Goel, and Ranson, 1985). The purpose of this technical report is to provide investigators with a detailed summary of data suitable for bidirectional reflectance and canopy reflectance modeling studies.

AGRONOMIC MEASUREMENTS

A commercial soybean field located approximately 13 km north-west of West Lafayette, Indiana was used for this study. The field was selected on the basis of uniformity in terms of slope ($< 2\%$), soil type, drainage and planting pattern. The field was planted to soybeans (Glycine max, (L.) Merr. "Calahan 9250") at a seeding rate of 62 kg/ha in north-south oriented rows. The row spacing was 76 cm with a mean population density of 28 plants/m^2.

Agronomic data were acquired on three dates following spectral measurements during the summer of 1980. On the first two dates (July 18 and July 25) the soybean canopies were incomplete with well defined

rows. By the third date (August 28) the canopy was completely closed and exhibited minimal row structure (Figure 1).

Agronomic measurements describing the canopies were acquired within one day of the spectral measurements. These data included leaf area index (LAI), total fresh and dry phytomass, stage of development, percent canopy cover, canopy height, canopy width, leaf angle distribution and leaf spectral reflectance and transmittance.

Soybean phytomass and leaf area index were estimated from random samples of one meter lengths of row. The leaf area of a subsample of green leaves from each sample was obtained with an optical planimeter (LICOR Model LI-3000) and dry weights were obtained. LAI was estimated from a subsample of leaves and was based on the leaf area to weight ratio and the ground area of the sample. Stage of development was determined from ten plants using the Fehr and Caviness (1977) scale. Percent canopy cover was estimated by projecting a 35 mm color slide acquired from nadir onto a dot grid and calculating the percentage of dots hitting vegetation. Canopy cover represents the vertically projected foliage area. Canopy height and width were measured to the top leaf and the width across the row at the mid-height of the canopy, respectively. Table 1 summarizes the agronomic measurements for the three dates.

Soybean leaf angle measurements were made using a modification of the protractor method described by Nichiporovich (1961) and Kyle and Davies (1974). in addition to leaf inclination and azimuth angles, the three-dimensional locations (X,Y,Z) and leaf area were measured for each leaf sampled (except for the August 28 date when only leaf heights (Z) and leaf areas were obtained). A detailed description of the foliage geometry measurement procedure can be found in the next section.

CANOPY GEOMETRY MEASUREMENTS

Three-dimensional characterization of the soybean canopy was accomplished by measuring leaflet orientation (inclination and azimuth angles), as well as leaflet heights, distances from mid-row and distances along row as referenced to a 1.0 m x 1.3 m board with a grid of meter sticks attached to it. The location of the sample was random and the measurement board was placed at this location in the furrow halfway between adjacent rows. A windbreak was constructed to protect the sample from wind. The board was leveled and positioned vertically. The distance between the bottom of the board and the base of the plants was measured to correctly determine the leaflet heights. All leaflets within a 25 cm length of row were sampled starting with the uppermost leaf and progressing downward. Leaflet inclination angles were determined with an inclinometer similar to those described by Nichiporovich (1961) and Kyle and Davies (1974). Azimuths were measured with a simple apparatus consisting of a small plate equipped with a circular bubble

level and a dowel attached perpendicular to the face of the plate. A reference mark on the bubble level plate was oriented towards true north and the plate held parallel to the upper leaflet surface. The bubble level was graduated into 45° segments with the position of the bubble 0 indicating the azimuth $+ 180^O$. With the azimuth device still in place, the inclinometer was held parallel to the perpendicular dowel on the plate, thus indicating the angle from vertical to the leaf normal. The recorded angle was later converted to inclination. After the angle measurements were made, a meter stick was placed above the leaf and the distance from the center of the leaflet to the measurement board was recorded. With the meter stick perpendicular with the measurement board, the distance from a reference point on the board to the center of the leaflet and the height of the leaflet was recorded. The leaflet was then removed from the plant, numbered with a felt marking pen, and placed in an ice chest for leaf area measurement. Individual leaf areas were determined with an optical leaf area meter later the same day in the laboratory.

The geometry estimation procedure was performed simultaneously by two teams at different locations in the field. The measurements required about 2 hours to complete. All destructive sampling was conducted outside the total field of view perimeter for the reflectance measurements.

The canopies were stratified into 10 cm horizontal layers. The fractional LAI (FLAI) within each layer was calculated as the accumulated leaf area in a layer divided by the total leaf area. The fractional leaf area was then multiplied by the average LAI for a canopy as given in Table 1 to obtain the LAI in a given layer (XLAI) (Table 2).

The canopy was further stratified into leaf inclination angle bins of 10°. The fractional leaf area for a given inclination angle bin and canopy layer was calculated as above. Tables 3-5 present the FLAI and number of leaves sampled for each leaf inclination angle bin and layer for the three canopies. Finally, the combined leaf angle probability densities and cumulative leaf angle frequency distributions for each canopy are presented in Table 6.

SOYBEAN CANOPY OPTICAL PROPERTIES

Plant canopy part (leaves, stems and pods) reflectance and transmittance data were obtained in the laboratory with a Beckman DK-2 spectrophotometer on 29 August 1980. To maintain the plant in good condition the plants were removed from the field with a substantial root ball in well watered containers and transported to the laboratory in an enclosed vehicle. Table 7 presents the average directional-hemispherical reflectance and transmittance of five random samples for soybean leaves from 450 to 1125 nm. Average directional-hemispherical reflectance for five samples of pods and mats of stems are also presented. Standard

deviations of the measurements are also given in Table 7. Table 8 lists the results for individual Exotech Model 100 wavelength band based on the DK-2 measurements (Table 7); Exotech responsivity (Figure 2); spectral irradiance of sunlight (Figure 3); and reflectance of a barium sulfate panel measured in the laboratory (Tables 9 and 10).

SOYBEAN FIELD REFLECTANCE FACTOR MEASUREMENTS

Spectral radiometric data for the soybean sun-view angle experiment were acquired with an Exotech Model 100 radiometer. The instrument has four spectral bands, 500-600nm, 600-700nm, 700-800nm, and 800-1100nm, corresponding to the bands on the Landsat MSS. Field stops were used to restrict the half power angular field of view (FOV) to 10°. The instrument was attached to a mount capable of movement in the horizontal (azimuth) and vertical (zenith) planes. A truck with an extendible boom provided an aerial platform for the instrument at a nominal altitude of 10 m above the soil surface. Measurement hemispheres of radiometric data were acquired through all combinations of nominal view zenith angles (θ_v) of 0, 7, 22, 30, 45, and 60° and view azimuth angles (ϕ_v) of 0, 45, 90, 135, 180, 225, 270, and 315° as described by Ranson et al. (1981). The instrument was also positioned over a plot cleared of vegetation where bare soil reflectance was measured (Table 12).

These data were acquired at hourly intervals through the day under a variety of solar zenith (θ_s) and solar azimuth (ϕ_s) angles as long as sky conditions permitted (i.e. no clouds). Prior to and after each hemisphere of measurements, calibration measurements were acquired from a painted barium sulfate panel illuminated under the same conditions as the canopy to provide for calculation of reflectance factors (RF) (Robinson and Biehl, 1979). Calibration data were corrected to account for non-Lambertian reflectance properties of the panel at larger solar zenith angles. Shaded panel measurements were also made to estimate the percent skylight in the visible (500-600nm, 600-700nm) bands (Table 13). Color photographs (35 mm) were taken at each canopy and soil view position to document the field of view. A summary of the data sets collected is provided below in Table 11. A diagram of the coordinate system used is presented in Figure 4.

The soybean canopy reflectance factor data are listed in the Appendix as a set of matrices with the columns of view zenith angles and rows of view azimuth angles. Because of a non-level instrument platform the nominal view zenith angles were as shown in Table 14 for the 17 July data and Table 15 for the 24 July data. The equipment was modified to level the instrument platform, so no adjustments are required for the 27 August data.
