Title:   **INTEGRATION OF REMOTE SENSING AND GEOGRAPHICAL  
INFORMATION SYSTEMS FOR AGRICULTURAL  
REASSESSMENT<sup>1</sup>**

Authors:   *R. Norberto Fernández, D. Fabián Lozano-García,  
and Chris J. Johannsen.*

University, West Lafayette, Indiana 47907.

Submitted to:   *Photogrammetric Engineering & Remote Sensing.*

<sup>1</sup>Contribution from the Agronomy Dep., Purdue Univ. Agric. Exp.  
Stn., West Lafayette, IN 47907. Journal paper no. \_\_\_\_.

1 thirty counties, contains county soil survey data,  
2 agricultural land ownership maps, land use maps, several soil  
3 attributes, and other variables, stored in database files.  
4 Selected macros allow to produce printouts of interpretive  
5 maps and reports (Santini et al., 1989).

6 Although this system is able to produce different  
7 outputs (such as interpretive soil maps, land ownership maps  
8 and tables, land use maps and tables, and farmland valuation  
9 tables), technical limitations influenced the original  
10 design, thereafter, restricting its potential expansion, the  
11 possibility of integrating data from different sources for  
12 modeling, and the link to other systems.

13 Geographic information systems are useful tools to  
14 integrate different data for local land planning (Niemann et  
15 al., 1987; Ventura, 1988), and natural resources management  
16 (Walsh, 1985). Remote sensing is also a valuable tool for  
17 mapping, monitoring and modeling agricultural and other  
18 natural resources (Bauer et al., 1978; Estes, 1985). Recent  
19 developments in commercial technology allows to process and  
20 exchange data between remote sensing analysis and geographic  
21 information systems, at acceptable cost (Ehlers et al.,  
22 1990). This functional integration, which is also available  
23 for microcomputer-based systems, opens the possibility to  
24 local agencies of integrating data and automating many  
25 cartographic tasks in an efficient and timely way. The  
26 Laboratory for Applications of Remote Sensing (LARS) at  
27 Purdue University is assisting Miami county officials in the

1 use of these technologies for farmland reassessment, soil  
2 erosion mapping, and soil management.

3 The objective of this study was to utilize remote  
4 sensing and geographic information system technologies to  
5 develop a model for agricultural land appraisal in Miami  
6 county, Indiana. The model had to: 1) comply with state and  
7 county laws; 2) be accurate at the 90% level; 3) be efficient  
8 in terms of data storage and data handling; and 4) be  
9 flexible in presenting results, i.e. the model should be able  
10 to show results on county, section, and individual farm  
11 basis, and it should be able to display results in map and  
12 tabular format. Additionally, all operations and processing  
13 had to be performed on microcomputers. The results obtained  
14 from this model will be used by the Miami County officials in  
15 the agricultural reassessment.  
16

#### 17 **BACKGROUND**

18 The underlying idea of the Indiana farmland reassessment  
19 is that land should be valued according to its productive  
20 potential rather than its market value. Productive potential  
21 takes into account, first, the capacity of the soil to  
22 produce crops (soil productivity); second, the land cover  
23 type; and third, possible reductions in cropland productivity  
24 caused by river or stream flooding.

25 Each soil map unit is given a soil productivity factor  
26 (SPF) for use in the farmland reassessment. SPFs, which  
27 refer to the capacity of the soil to produce crops, are

1 calculated based on soil properties such as slope, water  
2 holding capacity, natural drainage, organic matter content,  
3 etc.; and corn yield estimates over a 10 or 15 year period.  
4 In Indiana, corn yields estimates are the most reliable yield  
5 estimates available for all types of soils.

6 The land types defined for the farmland reassessment  
7 are: *tillable land*, land used for cropland or pasture with no  
8 impediments to routine tillage; *non-tillable land*, land with  
9 brush or scattered trees with less than 50% canopy cover or  
10 impediments for crop production; *woodland*, timber with 50% or  
11 more canopy cover; *other farmland*, farm buildings, farm ponds  
12 or running water; *agricultural support land*, public ditches  
13 and roads; *homesite*, land area for residential homesite.  
14 More productive land is rated higher than less productive  
15 land and thus, will have a higher assessed value (State Board  
16 of Tax Commissioners, 1986).  
17

## 18 MATERIALS AND METHODS

### 19 HARDWARE AND SOFTWARE

20 The model for land appraisal was developed on  
21 microcomputer-based systems. The GIS was developed on a PC-  
22 ARC/INFO<sup>1</sup>, and the analysis of satellite data was performed on  
23 a PC-ERDAS<sup>2</sup>. The ARC/INFO software was used to convert files  
24 from raster to vector format.  
25

<sup>1</sup>ARC/INFO is a trademark of Environmental Systems Research Institute, Inc. (ESRI), Redlands, California.

<sup>2</sup>Earth Resources Data Analysis System, Atlanta, Ga.

1   **DATA INPUT AND CARTOGRAPHIC BASE**

2           Several maps were used to build the spatial database  
3   (Table 1); they were redrafted on stable base (MYLAR®) and  
4   manually digitized using a GTCO<sup>3</sup> Digipad 2436A digitizing  
5   tablet, configured to encode coordinates in ASCII format with  
6   an accuracy of +/- 0.01 inch.

7           The cartographic reference layer of this GIS are stable-  
8   based USGS 7.5 minute series topographic maps (scale  
9   1:24000). Details on accuracy of registration and geodetic  
10   reference can be found in Fernández *et al.* (1991). Locations  
11   of all features were expressed in terms of the Indiana State  
12   Plane Coordinate System (Curtis, 1974). The model was  
13   evaluated on sections 3, 4, 9, and 10, T28N, R5E, Miami  
14   county, Indiana.  
15

16   **REGISTRATION AND ANALYSIS OF SATELLITE DATA**

17           Land cover maps were derived from digital analysis of  
18   satellite data. Several Landsat TM and SPOT scenes obtained  
19   at diferent dates throughout the growing season were used for  
20   temporal analysis. Each image was geometrically corrected  
21   using 220-250 control points for the entire County, and  
22   registered to the common base with sub-pixel accuracy (RMS =  
23   0.25 pixel; 7.5 m). The analysis procedure included:  
24   development of training statistics using the supervised and  
25   unsupervised methods, refinement of training statistics,  
26   classification of test areas, correlation between spectral

1 and informational classes, and the evaluation of  
2 classification results (Bauer et al., 1978). After the  
3 classification was accepted, the final classes were recoded  
4 for the reassessment, polygons smaller than 0.4 ha (1 acre)  
5 were eliminated, and the map was transformed from raster to  
6 vector format using the ARC/INFO's software. The final map  
7 was then incorporated into the GIS spatial database (Fig.1).  
8

### 9 DATABASE DESIGN

10 The database design process can be stated as follows:

11 "Design the logical and physical structure of one or more databases to accomodate the  
12 information needs of the users in an organization for a defined set of applications"

13 (Elmasri and Navathe, 1989).

14 The success in delivering information to satisfy those  
15 user's needs depends, in part, on the quality and  
16 availability of the data that reside in the system. To  
17 accomplish this, using ARC/INFO, it is necessary to design  
18 the cartographic layers, the feature attribute tables, lookup  
19 tables, and the map library (Chambers, 1989). In this paper,  
20 we will refer to the digital cartographic layers (with  
21 topology built in them) as the *spatial database*, and to the  
22 feature attribute tables as the *attribute database*.

23 For the spatial database, rural parcel and soil maps  
24 were digitized as polygon layers; while roads were digitized  
25 as line layers. Streams were digitized as line and polygon  
26 layers: at the scale of 1:24000, the main river in the area  
27 can be represented as a polygon (Fig. 1). Coverages (layers)

1 were organized on Section basis, as required by the County  
2 officials. Each Section is 2.6 km<sup>2</sup> (1 sq.mile), and covers  
3 259 ha (640 acres), approximately.

4 Attribute databases were designed to store descriptive  
5 information related to each map. A high-level conceptual  
6 model (the Extended Entity-Relationship model) was applied to  
7 create a schema, which reflects the semantics and constrains  
8 of the databases (Elmasri and Navathe, 1989; Chen, 1976).  
9 These conceptual models were then mapped into the relational  
10 data model and implemented in the INFO database management  
11 system.

12 Thematic data and attribute data are related through  
13 polygon identifiers; therefore, queries can be performed  
14 interactively from the spatial database or within the  
15 relational database (Morehouse, 1985).  
16

## 17 **RESULTS AND DISCUSSION**

### 18 **THE MANUAL APPROACH TO LAND APPRAISAL**

19 The current approach to the appraisal of agricultural  
20 land for property tax purposes in most Indiana counties,  
21 involves several steps (Fig. 2). Land ownership maps showing  
22 rural property boundaries, on section basis, are manually  
23 drawn at the scale of 1:4800 from information contained in  
24 the deeds. Roads and ditches are also included in these  
25 maps. Soil maps published at the approximate scale of  
26 1:20000 (Deal, 1979) are photomechanically enlarged to match  
27 the 1:4800 scale. Black and white aerial photographs taken

1 at the approximate scale of 1:24000 are enlarged and  
2 rectified to 1:4800 scale. The error of this rectification  
3 is 0.05 cm. Maps showing different land cover types are then  
4 created by visually interpreting these photographs. Once  
5 these three basic layers of information are obtained, the  
6 next step is to manually overlay them to create a new map  
7 showing the combination of rural property boundaries, soils,  
8 and land cover types. The areas of the different polygons  
9 are then manually measured with a planimeter and reported,  
10 for each parcel, in the Indiana Agricultural Property Record  
11 Card (IAPRC; Fig.2). The rest of the land ownership  
12 information needed to complete the IAPCR is obtained from an  
13 automated attribute database implemented in a microcomputer.  
14 Soil productivity factors are directly inputted into the  
15 IAPRC for each map unit.

16 Several problems were identified with this approach.  
17 The cartographic procedure lacks adequate quality control.  
18 This was more noticeable in the rural property maps where  
19 numerous inconsistencies were observed; among them, the number  
20 of parcels shown on maps did not always agree with the number  
21 of parcels stored in the attribute database; some parcel  
22 perimeters and areas shown on maps were different from the  
23 ones reported in the deeds (this problem was more noticeable  
24 for parcels that have natural features as boundaries); the  
25 areas of some sections did not correspond with the areas  
26 reported in the cadastre.

1           This manual approach requires that the original maps be  
2 subjected to a series of enlargements and scale changes;  
3 consequently, the final maps and the information derived from  
4 them contain different errors. There is a noticeable  
5 mismatch among similar features of the three layers, such as  
6 corner sections, roads, and rivers (Fig. 3). When soil maps  
7 are enlarged from their original scale to 1:4800 scale  
8 (approximately 5X), the lines that represent soil boundaries,  
9 in the resulting maps, have a width of approximately 1 mm,  
10 which at the scale of 1:4800 translates into 4.8 m (15.75  
11 ft). Area measurements derived from these maps will contain  
12 errors associated to that line width. Furthermore, all  
13 discrepancies among features in the final maps are visually  
14 adjusted; this results in additional error and lack of  
15 consistency during the calculation of polygon areas. The  
16 final outcome are maps that contain a mixture of errors from  
17 different sources, which in many cases lack the accuracy  
18 required by the Assessor's office ( $\geq 90\%$ ).

19           Several problems were also identified in the ownership  
20 attribute database, such as redundant information, empty  
21 records, unnecessary data, and inefficient storage and  
22 retrieval of data due to a lack of design. Because this  
23 database is not integrated with the rest of the appraisal  
24 procedure, attribute information can only be reported in  
25 tabular format and independently from the cartographic  
26 representation of the information. Furthermore, the current  
27 approach does not allow to integrate data from other sources

1 that could be used for analysis and modeling of rural  
2 resources.  
3

1 **THE GEOGRAPHIC INFORMATION SYSTEM APPROACH TO LAND APPRAISAL**

2 In order to avoid the problems originated with the  
3 current manual approach, and to enhance the appraisal of  
4 agricultural lands, we have developed an automated procedure  
5 based on the geo-relational model (Fig. 4). Within this  
6 model, locational data can be represented with the  
7 topological model, while thematic data processing can be done  
8 with the relational model (Morehouse, 1985).

9 For the spatial database (Fig. 1), all layers of  
10 information were registered to stable-based USGS 7.5 minute  
11 series maps. Land cover maps were obtained from satellite  
12 data, as described in **MATERIALS AND METHODS**, transformed from  
13 raster to vector format, and incorporated into the spatial  
14 database. Because of the inaccuracies that were detected in  
15 some of the original property maps, they were re-drafted on  
16 stable base at the scale of 1:24000, and then digitized.  
17 Soil maps, published at 1:20000 scale on uncontrolled aerial  
18 photography, were also re-drafted on stable base at 1:24000  
19 scale, and digitized. During this scale conversion, minor  
20 adjustments were done to some of the soil delineations to  
21 match the topography. Roads and railroads were digitized  
22 directly from the USGS 7.5' Quad maps. The drainage network  
23 was obtained from different sources (USGS Quad maps, aerial  
24 photographs, soil maps, and property maps), drafted on stable  
25 base at 1:24000 scale, and then digitized.

26 These digital layers were then used as input for the  
27 land appraisal model, and to generate different maps using

1 the software standard functions. State statutes mandate that  
2 a strip of land of 22.85 m (75 ft) each side of a legal drain  
3 (ditch) be used for maintenance of the drain; and, therefore,  
4 are not taxable to the affected landowner. These "easements"  
5 can be subtracted during the calculations for the tax  
6 assessment. Also, 6.10 m (20 ft) each side of a road are  
7 used for maintenance (right of way). Proximity analyses were  
8 performed on roads and drainage maps in order to calculate  
9 easements and right of ways. The resulting maps were  
10 combined with the overlay of property boundaries, soils, and  
11 land cover to show the combination of these variables on  
12 section and individual farm basis (Fig. 4).

13 The attribute databases were redesigned and/or enhanced  
14 to accomodate more information. The rural *land ownership*  
15 database contains information about owners (persons,  
16 corporations, organizations, and estates), as well as legal  
17 descriptions of parcels. We have also designed a new  
18 database for *soils*, which contains information about the  
19 fifty soil mapping units present in Miami county. This  
20 information describes soil surface conditions, soil pedons,  
21 pedon sites, and soil horizons. Data were coded for input,  
22 and lookup tables were defined for display of the data. The  
23 soil database was loaded with data provided by the USDA Soil  
24 Conservation Service (Forms 5 and 6) in Indianapolis,  
25 Indiana. SCS files were reformatted to INFO format, and  
26 adapted to the new design. Similar soil information can be  
27 found in published soil survey reports (Deal, 1979). Soil

1 productivity factors were also included in this database.  
2 The resulting databases are free from update anomalies, while  
3 preserving all dependencies among attributes. Since these  
4 databases are part of the GIS, they can be accessed from the  
5 spatial database through software routines, or from the DBMS  
6 independently. Details on the design and implementation of  
7 these databases can be found in (Fernández and Rusinkiewicz,  
8 1991; Fernández *et al.*, 1991 a and b).

9  
10 Some advantages of this GIS approach, as compared to the  
11 current manual approach, can be readily observed. The  
12 registration of all layers to a base map provides an accurate  
13 and efficient positioning of spatial features; therefore,  
14 allowing compatibility for the resulting products. Common  
15 features, such as rivers, roads, and corner sections, can be  
16 digitized only once in a template, and copied to subsequent  
17 layers when needed. This eliminates the problem of  
18 mismatches among layers.

19 All area measurements are done automatically by the  
20 system, eliminating the problem of line thickness and visual  
21 adjustments. The final results can be shown in map and  
22 tabular format; and, they can be incorporated into the IAPRC  
23 for further calculation of farm taxes (Fig. 5 and 6).

24
