15. Supplementary Notes

16. Abstract

The purpose of this effort was to identify the locations of the sample segments for the 1978-79 Multicrop experiments to support:

-Development and evaluation of procedures for using LACIE and other technologies for the classification of corn and soybeans.

-Identification of factors likely to affect classification performance.

-Evaluation of problems encountered and techniques which are applicable to the crop estimation problem in foreign countries as well.

In order to meet these requirements, two types of samples were selected. Low density segments were distributed throughout corn and soybean producing areas to sample all variations of conditions which could affect classification accuracy and to more completely represent conditions which might be found in other countries. High density segments were selected in smaller areas to support the investigation of training, classification, and area estimation procedures on a smaller scale for possible use in future Multicrop experiments.

In this report, the data set and methods employed in the stratification are discussed. Rationale, methods, and results for both the low and high density segments are discussed.

STRATIFICATION AND SAMPLE SELECTION FOR MULTICROP EXPERIMENTS

1. Introduction.

In February 1978, LARS was asked to participate in the stratification and sampling tasks for the transition year experiments. The project was supported by personnel and funds from two tasks of NASA Contract NAS9-15466: "Application of Statistical Pattern Recognition to Image Interpretation" and "Application and Evaluation of Landsat Training, Classification, and Area Estimation Procedures for Crop Inventory."

The purpose of this effort was to identify the locations of the sample segments for the 1978-79 Multicrop experiments to support:

- Development and evaluation of procedures for using LACIE and other technologies for the classification of corn and soybeans.
- Identification of factors likely to affect classification performance.
- Evaluation of problems encountered and techniques which are applicable to the crop estimation problem in foreign countries as well.

In order to meet these requirements, two types of samples were selected. Low density segments were distributed throughout corn and soybean producing areas to sample all variations of conditions which could affect classification accuracy and to more completely represent conditions which might be found in other countries. High density segments were selected in smaller areas to support the investigation of training, classification, and area estimation procedures on a smaller scale for possible use in future Multicrop experiments.

In this report, the data set and methods employed in the stratification are discussed. Rationale, methods, and results for both the low and high density segments are discussed.

2. Objectives

In order to support the corn and soybean experiments, two types
of segments were selected: low density segments and high density seg-
ments. Different issues can be addressed using each type of segment.

The low density segments were selected to cover a wide range of
conditions under which areas will have to be classified in larger
Multicrop efforts to allow possible problems. to be examined (e.g.,
in algorithms, systems, data acquisition). The low density samples
were located in 14 states in the U.S. corn and soybean producing areas.
This region was divided into eight strata according to the level of
county production of corn and soybeans and average farm size. Twenty
segments per stratum were selected. The distribution of these seg-
ments permits the calculation of variability within a stratum to pre-
dict the variability of aggregated estimates of corn and soybeans in
the U.S. and to determine the optimum allocation of samples for mak-
ing such estimates. The allocation of these samples was not designed
for, and thus does not support, making aggregated estimates.

The high density samples are located in four test sites in high
production areas of the U.S. Corn Belt. Twenty segments were selected
from each test site which is approximately ten counties in size. The
increased density of samples permits estimation of the local variabil-
ity in high production areas. These samples support the investigation
of training, classification, and area estimation procedures on a
smaller scale for possible use in future Multicrop experiments. Other
area estimation procedures such as regression estimation can be evaluated
and county level estimates can be assessed.

3. Data Set Description

The data used in this study were acquired by the Statistical
Reporting Service of the U.S. Department of Agriculture (USDA/SRS).
Two types of data were available: the USDA/SRS county estimates for
1972-76 and the 1974 agriculture census data. The data were supplied
by NASA/Johnson Space Center (NASA/JSC).

The SRS dual county estimates program data for 1972-76 were available. Under the Federal program, county estimates are prepared for specified crops, states, and counties. These estimates include the major crops produced in most states. Some of the state statistical offices prepare county estimates for a few crops not required under the Federal program in cooperation with their respective state governments, but these estimates were not available on tape.

Variables which were included in the county estimates data set were: state, crop reporting district, county, year data was punched, crop year, commodity code, acres planted, acres harvested, yield per harvested acre, and production(Figure 1). Counties from the entire U.S. were represented. The commodities for which information was available are listed in Table 1. Some problems encountered with this data set are discussed in the appendix.

The 1974 agriculture census data were supplied for 14 states in the U.S. corn and soybean producing regions. These data included: number of acres in each county, average farm size by county, and the land in farms for each county.

4. Stratification

The first step in selection of sample segments was the stratification of the area to be studied. The variables used in the stratification, the rationale and methods employed, and the results of the stratification will be discussed in this section.

Variables Used in Stratification.

The variables available were those contained in the USDA/SRS county estimates program (Figure 1) and the selected variables from the 1974 agriculture census which were supplied by NASA/JSC. The variables which were considered for use were: acres planted, acres harvested, yield, and production for the crops listed in Table 1; acres in a county; percent agricultural area (land in farms) in a county; and average farm size by county. From these variables, the

number of agricultural acres in a county was computed by multiplying
the percent agricultural area by the county acreage. Normalized pro-
duction of a crop for a county was computed by dividing the five-
year average production of that crop by the agricultural acres in
the county.

In order to fulfill the objectives, the stratification was per-
formed using three variables: normalized production of corn, normal-
ized production of soybeans, and average farm size. The first two
variables were selected to make strata which are homogeneous with
respect to the relative importance of corn and soybeans in the agri-
cultural scene. The average farm size was selected to represent
problems which might be encountered in Landsat data classifications
with different field sizes.

Methods of Stratification.

The rationale for the stratification method was based upon the
objective of creating eight strata in the United States corn and
soybean producing regions which were relatively homogeneous with
respect to the relative importance of corn and soybeans in the agri-
cultural scene and the average farm (or field) size. These strata,
then, represent several conditions under which Landsat data will have
to be classified in Multicrop studies. Samples selected from these strata
will be representative of conditions found throughout the corn and
soybean producing regions.

The first step in the stratification was a reduction of the data
set size. Only the 14 states for which the agriculture census data
were supplied were considered. Counties with neither corn nor soybeans
were omitted.

The joint distributions of normalized corn and soybean productions
and average farm size were examined. The average farm size was
represented in two groups: small farms (average size less than or
equal to 190 acres) and large farms (size greater than 190 acres).

About one-third of the counties were in the small farms category
and about two-thirds were in the large farms category. The division
into these two groups was somewhat arbitrary although there was a
break in the continuum of data at about 190 acres.

For each farm size, the normalized corn and soybean productions
were displayed in deciles to look for broad clusters of data. The
strata were determined by examining tables of the distributions of
these variables. Three strata of small farm counties and five strata
of large farm counties were selected to represent the two farm sizes
approximately proportionally to the number of counties in them.

Counties which fell in the lower 10% of all counties in both
corn and soybean production were omitted from consideration.
Counties which fell outside the broad clusters of data were not included
in any stratum. Thirteen counties satisfying all other selection
criteria were outliers from the clusters and were not included. A
schematic diagram (Figure 2) shows the methodology employed in the
stratification . Table 2 gives the definitions of stratum boundaries.

Results of Stratification.

Eight strata covering 14 states in the U.S. corn and soybean
producing region were determined. The counties in each of these
strata are shown in Figures 3 to 10 and are listed in Tables
3 to 10.

The large farm, highest production stratum (stratum 8) is geo-
graphically located at the center of the Corn Belt. Strata 7, 6, and
4 are located around its perimeter outward according to decreased
production. In these strata of large farms, corn and soybeans are of
approximately equal importance.

Stratum 5 is located geographically apart from the other strata
with large farms. This stratum, in which soybeans have a greater

importance than corn, is located in the Mississippi River Valley
where the climate and soils are more suited to soybeans than to corn.

Stratum 3, the small farm stratum with the greatest production
of corn and soybeans, is located primarily in eastern Indiana and
western Ohio where the cropland is productive, but the terrain is
rolling. The lesser production small farm strata (strata 1 and 2)
are centered about this area on the outskirts of stratum 3.

In summary, looking at the geographic location of the strata,
the system appears to be logical and the various strata seem to
represent different conditions. This result is supportive not only
of the variables and the methodology employed in the stratification,
but also of the validity of the data sets employed.

5. Low Density Segments

Sample Allocation.

The low density segments were selected to sample the variability
present in corn and soybean producing regions of the United States.
The sample was designed to represent differences in climate, topography,
field size, variety, and management practices. In order to achieve as
diverse a representation as possible, an equal number of segments were
allocated to each of the strata. This allocation scheme emphasizes
representation of variability rather than sampling in a manner suitable
for aggregation purposes.

Twenty 5 x 6 nautical mile segments were allocated to each stratum.
The counties to receive sample segments were determined using a random
selection procedure without replacement. Thus, all counties in a
stratum had an equal probability of receiving a sample and no county
could contain more than one segment. Locations of counties receiving
sample segments are illustrated in Figure 11. Latitude and longtitude
coordinates of the sample segment centers can be found in Table 11.
Figure 11.   Locations of counties in all eight strata receiving low density sample segments.

Segment Location.

Segment locations were selected using a modification of a computer program written for "Crop Inventory Using Full-Frame Classification", described in the final report of Contract NAS9-14970 (June, 1977). The design of the location procedure was based upon that used in LACIE. A grid was laid over each county with grid intersections five by six nautical miles apart. A random selection procedure was then used to select a grid intersection which determined the latitude and longitude coordinates of the center point of each segment.

Although only one segment was allocated to each county, several segments were selected to attain a high probability that at least one of them would be located in an agricultural area and would be accepted as a site. The number of sites to be located in each county was determined by the percent agricultural land in the county. The segment centers were randomly selected without replacement and the first segment located outside a nonagricultural area was to be used.

The ag/nonag delineation was conducted by NASA/JSC. Full-frame color composite Landsat imagery was used to delineate areas which were not agricultural. This was done on the basis of whether or not field patterns were apparent. Rangeland, forest, and urban areas were among the types of land uses which were delineated as nonag. Segment locations were compared with these boundaries and the segment was rejected if less than 5% of the segment fell into an agricultural area.

6. High Density Segments

Test Site Selection.

The high density segments were designed for intensive study of the remote sensing technology required for corn and soybean inventories. In order to sample more corn and soybeans, test sites were located in the Corn Belt where production of both crops is high. Test sites were

placed across the Corn Belt to sample the varied climatic conditions, soil types, crop distributions, and field sizes which are present (Figure 12). Each test site was selected to be relatively homogeneous within (same stratum, similar soil types and farming practices) to support classification studies, particularly of multisegment training. Each of the sites contained about ten counties and was approximately the size of a crop reporting district.

Test Site 1 is located in eastern Indiana which is an area of small farms. The other three test sites are located in large farm areas. Test Site 2 is comprised of counties in west central Indiana and east central Illinois. Test Site 3 is in north central Iowa and Test Site 4 is in west central Iowa.

Description of Test Sites 1 and 2. The climate across central Indiana and east central Illinois is continental with warm summers and cold winters. Normal mean temperature is -1.2°C in January and 31.1°C in July. In this semihumid region of the U.S., the average annual precipitation is 950 to 1000 mm which does not limit crop production. Rainfall is greatest during the spring and early summer months with June typically receiving 107 to 118 mm of rain. Average precipitation in June is slightly excessive, adequate in July, and often inadequate in August for corn. The crops survive because of some moisture stored in the soil profile.

Test Site 1 is composed of two major soil associations. Soils of the northern two-thirds of this district (Allen, Wells, Adams, Blackford, Jay, and parts of Madison, Delaware, and Randolph counties) belong to the Blont-Pewano-Mortley soil association. These soils were formed on clayey glacial till and are nearly level and poorly to very poorly drained. The Brookston-Crosby-Miami-Parr assocation which predominates in the remainder of Test Site 1 was formed in thin loess (wind-blown materials) over loamy glacial till and is also poorly drained. These two soil associations are suited to intensive cropping but are subject to problems associated with wet soils unless adequate artifical drainage is provided. Typically, approximately 287,700 hectares of
Figure 12.   Locations of high density test sites.

corn for grain; 245,300 hectares of soybeans; and 87,300 hectares
of winter wheat are planted.

Test Site 2 includes dark-colored prairie soils and light-
colored forest soils both of which were formed in loess-covered
glacial till. Topography is generally gently rolling with short
slopes and nearly level areas interrupted by depressions or potholes.
The northern one-third of this district (Newton, Jasper, Kankakee, and
northern Ford and Iroquois counties) has soils which are sandy and
variable in subsoil development. These soils tend to be droughty,
low in fertility, and require a high level of management for moderate
yields. In Tippecanoe, Benton, Warren, southern Ford and Iroquois,
and northern Vermilion and Champaign counties in the central portion
of the district, the soils developed under prairie or mixed prairie
and forest vegetation, are dark to moderately dark colored, and are
generally imperfectly drained. Crop yields are moderately high to high
with a high level of management. Dark-colored soils on nearly level to
moderately sloping upland areas are typical in southern Vermilion
and Champaign counties. These soils have high available moisture
storage capacities and are very highly productive under a high level of
management. Farmers in Test Site 2 typically plant 667,700 hectares of
corn; 557,200 hectares of soybeans; and 39,200 hectares of winter wheat.

Description of Test Sites 3 and 4. The climate in western Iowa
is continental, characterized by marked seasonal changes. Temperature
fluctuations are extreme with winters being cold and summers warm.
Thirty-year normal temperatures are -8.4^0 C in January, the coldest month,
and 23.6^0 in July, the warmest month. Annual precipitation is 762 mm
with most of it occurring in the spring and early summer. Summer
precipitation is variable from year to year with the largest amount (132 mm)
generally falling in June.

The Clarion-Nicollet-Webster soil association, which is the only
major soil group in Test Site 3, was derived from glacial till. About
75 percent of the area has level to gently sloping topography and is
well suited to intensive production of corn, soybeans, and alfalfa.

This test site has about 1,499,600 hectares of farm land and typically grows 607,300 hectares of corn (approximately 96% for grain); 477,100 hectares of soybeans; and 54,500 hectares of alfalfa and hay.

Three major kinds of parent materials (loess, glacial till, and alluvium) are found in Test Site 4. Loess (wind-blown material) from the Missouri flood plains is thickest near the Missouri River and thins and increases in clay content in a southeasterly direction. Marshall and Monona-Ida-Hamburg soil associations which occupy the central three-fourths of this district were formed from deep loess under grass vegetation. These soils are generally well-drained and have high proportions of their area used for cultivated crops. The Clarion-Nicollet-Webster soil association, which is a continuation of the predominant soil of the third test site, is the major soil in Sac County. These soils are well suited to intensive production of corn, soybeans, and alfalfa. A third major group of soils which developed primarily from alluvial materials on the nearly level flood plains of the Missouri River are the Luton-Onawa-Salix association. These soils are found primarily along the Missouri River in Woodbury, Monona, and Harrison counties and are farmed for corn, soybeans, and wheat.

High proportions of Test Site 4 are used for cultivated crops, particularly corn and soybeans. Of the 1,385,100 hectares of farm land in this district, 634,100 hectares of corn are planted annually and approximately 90 percent of this corn is harvested for grain. An additional 233,700 hectares of soybeans are typically planted. The proportions of corn and soybeans vary from year to year depending on market conditions and prices.

Sample Allocation.

In general, two segments per county were allocated. In the case of unusually large or small counties, three segments or one segment might be allocated. All counties indicated in Figure 12 received segments. Table 12 lists the number of segments allocated to each county.

Table 12. Allocation of sample segments to counties in each of the
four high density test sites.

Sample Location.

The method used for sample selection was the same as described
for the low density samples. More segments were located than were
allocated to permit for loss of some segments in nonagricultural areas.
Locations of the sample segments by latitude and longitude coordinates
can be found in Table 13.

7. Summary and Conclusions

A stratification was performed and sample segments were selected
for an initial investigation of Multicrop problems. . The effort was to
support:

- Development and evaluation of procedures for using LACIE and
  other technologies for the classification of corn and soybeans.

- Identification of factors likely to affect classification performance.

- Evaluation of problems encountered and techniques which are
  applicable to the crop estimation problem in foreign countries
  as well.

The two types of samples, low density and high density, supporting
these requirements were selected as a research data set for an initial
evaluation of technical issues and should not be used in an aggregation
scheme. In summary, looking at the geographic location of the strata,
the system appears to be logical and the various strata seem to represent
different conditions. This result is supportive not only of the variables
and the methodology employed in the stratification, but also of the
validity of the data sets employed.

APPENDIX

Appendix. Problems Encountered with County Estimates Data

Numerous difficulties were encountered with the county estimates
data. The original tape which was transmitted from NASA/JSC was in ASCI
format on an 800 BPI tape.

There were some unreadable characters on the tape, indicating that
the original data tape may have been bad. The problems were found in
the first few columns of a record, so that "educated guesses" could be
made to fill in the missing information. The missing information was
sometimes restricted to the first five columns which were constant through-
out the entire data set. If state or county codes were missing, these
could be determined by examining the placement of the card in the data
deck. For all bad data lines, the missing information was overlaid, but
the first five columns (containing a constant code which was irrelevant to
the study) were left bad so that these lines could be located again if
necessary.

There were also some codes encountered which were not documented.
A visit with Bob Cole of the Indiana USDA/SRS office helped identify an
appropriate course of action.

The first column of each record was supposed to indicate the card
number and should have been "2" for all data on the tape. One record
was encountered, however, which had "3" in the first column. As it was
learned that card three did not exist, this was determined to be a key-
punching error and was changed on the data file.

Table A-1 lists crops and their codes for the data set. Nonexistent
commodity codes were encountered in the data files. Some of the unusual
codes might have been mispunched or might have been specific to a state;
an example of this type is the code 17163 (for class and crop code).
Class code 33 was not included on the list in Table A-1, but the Indiana
office of the USDA/SRS was able to inform us that this class code represented

Table A-1.   Commodity Codes.

Class	Crop Code	Utilization	Crop Name
10	119	9	Winter Wheat
10	129	9	Durum Wheat
10	139	9	Other Spring Wheat
10	199	9	Wheat, All
10	499	9	Rye, All
10	619	9	Rice, All
11	199	1	Corn for Grain
11	199	2	Corn for Silage
11	299	9	Oats, All
11	399	9	Barley, All
11	499	9	Sorghum, All
12	129	9	Cotton, All (Neither Ginning Status nor Staple Type Speoied)
12	121	9	Cotton, Upland
12	122	9	Cotton, American Pima
			Tobacco:
14	111	1	Flue-cured, type 11
14	111	2	Flue-cured, type 12
14	111	3	Flue-cured, type 13
14	111	4	Flue-cared, type 14
14	122	1	Fire-cured, type 21
14	122	2	Fire-cured, type 22
14	122	3	Fire-cured, type 23
14	133	1	Air-cured, type 31
14	133	2	Air-cured, type 32
14	133	5	Air-cured, type 35
14	133	6	Air-cured, type 36
14	133	7	Air-cured, type 37
14	244	1	Cigar-filler, type 41
14	255	1	Cigar-binder, type 51
14	255	2	Cigar-binder, type 52
14	255	4	Cigar-binder, type 54
14	255	5	Cigar-binder, type 55
15	299	9	Flaxseed
15	399	1	Peanuts
15	499	1	Soybeans
16	171	1	Dry Edible Beans - Pea (Navy)
16	171	2	- Great Northern
16	171	4	- Flat Small White
16	171	6	- Pinto
16	171	7	- Red Kidney
16	172	1	- Pink
16	172	2	- Small Red
16	199	9	Dry Beans (All Mich.)
16	319	9	Dry Peas - Smooth Green Kinds
16	329	9	- Yellow and White Kinds
83	161	8	Wrinkled Peas for Seed
16	599	9	Lentils
16	819	9	Austrian Winter Peas
36	129	9	Green Peas for Processing
37	829	9	Tomatoes for Processing
83	104	2	Bush Garden Seed Beans (Idaho)

miscellaneous vegetables. Another problem was class codes which matched
the list given, but whose corresponding crop code or utilization code
did not exist. The code "14558", for example, does not exist, but all of
class 14 is tobacco so this observation was included there. The utiliza-
tion "0" is not used for 10129 (durum wheat) but was included in that
crop type anyway. There were approximately 40 more cases which were
handled in a similar fashion.

Duplicate cards were also encountered in the winter wheat, corn,
barley, and miscellaneous crops data files. There were several different
varieties of duplicates. Some cards were exact duplicates, a situation
which had a straightforward solution. Some cards were encountered contain-
ing different estimates of a crop for the same county and the same year,
but which were punched in different years. In this case, the most recently
entered information was selected to be correct. Some duplicate cards had
a third type of problem: yields differed by a factor of ten while the rest
of the information was identical. In this situation, the card was selected
for which acres times yield was equal to production.

There were many zeros for acreage, yield, and production in the data
files. By looking at the values for a given crop in a given county over
the five year period, it was determined that a zero might represent two
situations: either no acreage of that crop was grown in that county or
the true data value was missing. Missing values could possibly have been
determined by consulting state crop production publications; time constraints
for this project, however, did not permit this type of verification. Years
with zero values were excluded from consideration in computation of crop
averages. If the data were indeed missing, this approach yielded a much
more realistic estimate. If the data were truly zero, a good estimate would
be obtained by averaging the other non-zero years which would be small numbers.

Additional steps in data verification were attempted by summing
individual estimates to obtain a total for a given crop, crop reporting

district, or state. These methods were abondoned as a data verification aid again due to resource considerations. As a rule, summing did not work. Some examples are given as follows.

Theoretically, the "all wheat" data file should be the sum of the winter wheat, durum wheat, and other spring wheat files. This was supposed to be true according to Bob Cole of the Indiana USDA/SRS office, but was found to be not necessarily true in the data. Sometines all wheat was larger than the sum of the three component files and sometimes the sum was larger. Occasionally, the numbers were about equal. Some counties reported total wheat, but did not divide it down into its components, while other counties appeared to do the reverse.

Finally, crop reporting district and state area and production estimates of a crop should be the sum of estimates for the counties comprising them. This check also failed frequently, a possible result of missing data or a mixture of preliminary and final estimtes.
